October 1985

The final version of this paper has benefited from the comments of Gary Burtless, the discussant for the paper. This paper was presented as part of the NBER conference on pensions held in Baltimore March 21-22, 1985. It was funded in part by the Department of Health and Human Services (HHS) grant #67A-83, and in part by HHS grant #84ASPE130A. The research reported here is part of the NBER's research program in Taxation and projects in Government Budgets, Pensions and Taxation and Capital Formation. Any opinions expressed are those of the authors and not those of the National Bureau of Economic Research.

The Determinants of IRA Contributions
and the Effect of Limit Changes

ABSTRACT

Tax-deferred savings are potentially an important component of savings for retirement and could represent a very substantial increase in tax-free savings for many employees. IRAs may also have a substantial effect on national savings. Total IRA contributions in 1982 were over 29 billion dollars. Despite the program's size and potential significance, little is known about the determinants of IRA contributions. This paper presents: (1) analysis of the effect of individual attributes on whether a person contributes, (2) analysis of the effect of individual attributes on how much is contributed, and (3) simulations of the effect of potential changes in contribution limits on the amount that is contributed to IRA accounts. Results of a similar analysis based on Canadian data are compared with results for the United States. Persons with low incomes are unlikely to have IRA accounts. In addition, after controlling for income, age, and other variables, persons without private pension plans are no more likely than those with them to contribute to an IRA. The analysis of Canadian data yields similar findings, and indeed specific parameter estimates for the two countries are very similar. Simulations based on the estimates suggest that the current Treasury Department proposal would lead to about a 30 percent increase in IRA contributions.

The Determinants of IRA Contributions
and the Effect of Limit Changes

by

Steven F. Venti

and

David A. Wise

To encourage employees not covered by private pension plans to save for retirement, individual retirement accounts (IRA) were established in 1974 as part of the Employee Retirement Income Security Act. Emphasizing the need to enhance economic well-being of future retirees and the need to increase national savings, the Economic Recovery Tax Act of 1981 extended the availability of IRA's to all employees and raised the contribution limit. Now any employee with earnings in excess of \$2,000 can contribute up to \$2,000 to an IRA account each year, with tax on the principle and interest deferred until money is withdrawn from the account. The combined contribution of an employee and a non-working spouse can be as high as \$2250. A married couple who are both working can contribute \$2000 each. Current tax proposals contemplate raising the individual IRA limit to \$2500 and the (non-working) spousal IRA limit from \$250 to \$2500.

Tax-deferred savings are potentially an important component of savings for retirement and could represent a very substantial increase in tax-free savings for many employees. Indeed, a \$2000 contribution to a retirement account represents a future pension benefit greater than many employer-provided private pension plans. The availability of IRAs may also have a substantial effect on national savings. According to IRS data, total IRA contributions in 1982 were over 29 billion dollars.

Despite the program's size and potential significance, surprisingly little is known about the determinants of IRA contributions. Thus the goals of this analysis are: (1) to analyze the effect of individual attributes on whether a person contributes, (2) to determine the effect of individual attributes on how much is contributed, and (3) to simulate the effect of potential changes in contribution limits on the amount that is contributed to IRA accounts. The results can be used to judge whether the goals that justified introduction of the program are being realized. In particular, persons who don't contribute to IRA accounts will not benefit from them. With national concern about the federal deficit, the short-run tax cost of the program is of substantial interest. The simulations suggest what this cost is and what the cost of proposed changes in the program would be. A fourth issue, the effect of tax-deferred savings on net individual saving, is not addressed in this paper but will be analyzed in future work.

The analysis is based on data obtained through a special supplement to the May 1983 Current Population Survey. Subsequent analysis will be based on the 1983 Survey of Consumer Finances and a special Carnegie Commission Survey of college and university employees.

Descriptive statistics on contributions to IRA accounts are presented in the next section. The statistical model that is used in the analysis is described in section II. The results are presented in section III. In section IV, results of a similar analysis based on Canadian data are compared with results for the United States. The Registered Retirement Savings Plan in Canada is a tax-deferred program that

incorporates the characteristics of both IRA and Keogh-like plans in the United States, although the contribution limits are quite different in the two countries. The same statistical model has been estimated on data from both countries.

The major empirical findings may be summarized briefly: tax-deferred savings plans are unlikely to be used by low-income persons. Thus they do not in general substitute for private pension plans, since higher-income persons are more likely than those with lower incomes to be covered by private plans. Given income and other individual characteristics, persons with private pension plans are no less likely than those without such plans to contribute to an IRA. The findings for Canada are very similar to those for the United States. Since the limits are very different, the similar findings provide support for the statistical specification.

Simulations based on the parameter estimates for the United States indicate that if the limits were increased in accordance with the recently proposed Treasury Department changes to the tax system, contributions would increase by about 30 percent.

I. Descriptive Statistics

Since model parameter estimates for the United States will ultimately be compared with those for Canada, the descriptive statistics in this section are presented for both countries. For several reasons, the data for the two countries are not strictly comparable, although they allow rough comparisons between the two countries.

Most contributions are made by middle income employees. Although 32 percent of employed persons in the United States have incomes below \$10,000, this group is responsible for only about 10 percent of total IRA contributions. Approximately 80 percent of contributions are made by persons with incomes between \$10,000 and \$50,000. Persons with incomes greater than \$50,000 contribute only about 10 percent of total contributions. In Canada, about 82 percent of contributions are made by individuals with incomes between \$10,000 and \$50,000 and about 15 percent by persons with incomes above \$50,000. Only 3 percent of contributions are made by those with incomes below \$10,000, as compared with 10 percent in the United States. (See table 1.)

As shown in table 2, only 5 percent of persons with incomes less than \$10,000 made an IRA contribution in 1982 in the United States, and only about 2 percent in Canada. The proportions of higher income groups making contributions are similar in the United States and Canada, although in general the proportions are lower in the United States than in Canada. Whereas the IRA program is new for most people in the United States, the Canadian RRSP plan was started in 1957.

Only 11 percent of all contributors in the United States have incomes less than \$10,000, 80 percent have incomes between \$10,000 and \$50,000, and about 9 percent have incomes greater than \$50,000. Again, the percentages in Canada are very similar to those in the United States. Seven percent of contributors have incomes less than \$10,000, about 88 percent have incomes between \$10,000 and \$50,000, and 7 percent have incomes greater

than \$50,000.

Proportions that contribute to the contribution limits in the two countries are shown in table 3. Because the contribution limits vary substantially between the two countries, the numbers must be viewed accordingly.¹ In neither country does the proportion contributing to the limit in any income group exceed 60 percent. In addition, women are apparently more likely than men to contribute to the limit in the United States, whereas in Canada the difference seems less apparent, although at least for persons with incomes below \$50,000 the proportion for women is greater than for men, with the exception of the zero to \$10,000 income group.

Average contributions in the United States range from \$75 for the lowest income group to \$1116 for those with incomes greater than \$70,000; while the average contribution of contributors ranges from \$1517 to \$1883. (See table 4.) This suggests that among those who contribute, a large proportion in each income group contributes at the limit. Unreported tabulations indicate that at very high income levels 85 to 90 percent of all contributions are at the limit. The percent of employees with contributions at the limit ranges from about 3 percent for low-income to 50 percent for high income employees. The figures for Canada are comparable, but the average contribution levels are considerably higher, reflecting the higher limits. In addition, the Canadian data pertain to both employees and self-employed persons, while the US data pertain only to employees and thus exclude contributions to Keogh plans.

tend to make somewhat larger contributions than those who are not, and they are also somewhat more likely to make contributions at the limit, as shown in table 5. In Canada, the limit on RRSP contributions increases with income and the maximum is higher for persons without than for those with a private plan. Thus for higher income persons, contributions are higher for those without private plans. Nonetheless, for most income intervals those with a private pension plan are more likely than those without one to contribute at the limit.

In summary: the descriptive data indicate that IRAs are typically not used by low income employees, and that they do not in general serve as a substitute for private pension plans.

II. The Statistical Model

The results suggest that relatively unambiguous answers can be provided to the three questions addressed in this paper. On the other hand, an analysis of the effect of tax-deferred accounts on net savings requires related but new and somewhat more complicated statistical procedures, and it seems apparent that the question will be answered only with more ambiguity and less confidence than the first three. Thus it is important to set forth the analysis so that questions that can be answered relatively precisely can be distinguished from those that inherently leave more room for doubt. To put in perspective the analysis conducted in this paper, it may be useful to illustrate how it is related to a more general analysis designed to estimate the net effect of tax-deferred accounts on individual saving. With this

goal in mind, a simple but general illustrative model is described first. It serves to motivate statistical analysis of each of the questions, while providing a framework within which the fourth question can be addressed. It demonstrates succinctly how the first questions are related to the fourth. The illustrative model also provides motivation for treating the first three separately from the fourth, although in principle, one general model could be used to address all the questions jointly. Estimation procedures designed to answer the first three questions are then considered, with particular attention to whether a correctly specified single behavioral equation can be used to describe both zero and positive levels of tax-deferred savings, or whether two behavioral relationships -- one describing whether a person is a potential contributor and the other the desired amount -- are required.

A. An Illustrative General Model

Decisions about the amount to save in various forms are undoubtedly made jointly so that one decision cannot be considered fixed while the other is made. In addition, unmeasured individual attributes are likely to affect saving decisions in each of two or more different forms. Thus persons who are observed to save more in one form are likely also to save more in another, not because savings in one form induce them to save more in another but rather because they were more inclined to save in any form. This means that one must disentangle the effects of individual specific attributes from the effect of savings in one form on savings in another.

The procedure outlined here addresses these problems by considering an individual's preferred allocation of current income to current consumption, tax-deferred savings, and other forms of saving, and then how observed choices are affected by the limit on the tax-deferred savings alternative. Based on such a model, it would be possible to simulate, for example, how total savings would be changed if the limit on tax-deferred savings were raised or lowered. The procedure relies heavily on the fact that the optimal savings behavior of individuals who are not constrained by the limit differs from the behavior of those who are, with statistical correction for the fact that persons who are at the limit, everything else equal, are likely to have a greater preference for saving than those who are not constrained; they are likely to save more in any form. In practice, the idea is to estimate the parameters of a "preference" function whose primary arguments are IRA contributions, at least one other form of savings, and current consumption. Associated with the preference function are optimal IRA contributions and optimal savings in other forms. In practice, it is necessary to choose these "demand" functions to fit the observable data, and then to choose the preference function consistent with them. The procedure can be illustrated based on a simple preference function.

To illustrate the idea, suppose that preferences for consumption and savings out of current income may be described by the simple form

$$(1) \quad V = (Y - S_1 - S_2)^{1-\beta_1-\beta_2} S_1^{\beta_1} S_2^{\beta_2}$$

where Y is income, S_1 and S_2 are tax deferred savings and other savings respectively, and β_1 and β_2 are parameters to be estimated. This function

is intended to represent preferences over possible allocations of current income conditional on individual attributes like income and age, and individual perceptions of the riskiness of different forms of savings.² This approach allows inferences about the relationship of income allocation to age, without constraining the functional form to correspond to a particular life-cycle hypothesis. In practice, the parameters would depend upon measured individual attributes and would be allowed to vary randomly among individuals to capture unmeasured variation in individual preferences for current versus future consumption as well as different perceptions of risk, etc. In this simple case, the unconstrained optimal saving choices are

$$(2) \quad \begin{aligned} S_1 &= \beta_1 Y, \text{ and} \\ S_2 &= \beta_2 Y. \end{aligned}$$

But in fact, the optimal choice is subject to a constraint; S_1 contributions cannot be greater than the IRA limit L . Until this limit is reached, contributions obey the equations above. But more generally the S_1 and S_2 functions are of the form

$$(3) \quad \begin{aligned} S_1 &= \begin{cases} \beta_1 Y & \text{if } \beta_1 Y < L, \\ L & \text{if } \beta_1 Y \geq L, \end{cases} \\ S_2 &= \begin{cases} \beta_2 Y & \text{if } \beta_1 Y < L, \\ \frac{\beta_2}{1-\beta_1} (Y-L) & \text{if } \beta_1 Y \geq L. \end{cases} \end{aligned}$$

Thus there are two S_2 saving functions. As long as the IRA limit has not been reached, savings obey the optimizing rule $\beta_2 Y$. But after the limit is reached, the savings function is of the form $[\beta_2 / (1 - \beta_1)](Y - L)$. This illustration ignores the tax deferral that makes IRA's more attractive than alternative forms of retirement savings. Introducing the tax rate in the example changes the utility function to

$$(4) \quad V = [Y(1-t) - S_1(1-t) - S_2]^{1-\beta_1} S_1^{\beta_1} S_2^{\beta_2}$$

where, assuming that savings are small relative to income, t is the marginal tax rate. The optimal saving choices then become

$$S_1 = \begin{cases} \beta_1 Y & \text{if } \beta_1 Y < L, \\ L & \text{if } \beta_1 Y \geq L, \end{cases}$$

$$S_2 = \begin{cases} \beta_2 Y(1-t) & \text{if } \beta_1 Y < L, \\ \frac{\beta_2}{1-\beta_1} (Y-L)(1-t) & \text{if } \beta_1 Y \geq L. \end{cases}$$

In this formulation, the marginal tax rate does not affect S_1 (IRA) saving, unless it affects preferences for current versus future consumption through the parameters β_1 and β_2 . The empirical findings reported below suggest an uncertain effect of the marginal tax rate independent of income, even though the rate of return on the IRA does depend on the marginal tax rate.

In practice, the parameters β_1 and β_2 would be made functions of

individual characteristics like age, occupation, possibly income itself, the tax rate, and other conditioning variables that would be likely to determine individual preferences over possible allocations of current income. To estimate the model, it is also necessary to choose a stochastic specification for the β s. One also needs to choose a specification that allows optimal, or "desired", values S_1 and S_2 to be negative, since many individuals will not save in any form and indeed will borrow.³

As emphasized above, this particular functional form is only for illustrative purposes; the form that is ultimately chosen must be determined by the data. But the simple example demonstrates how changes in the limit may affect behavior. In particular, explicit reference to a preference function assures a specification of savings S_2 after the limit L on S_1 is reached that is internally consistent with the function that applies before the limit is reached. And, in a fully specified model, estimates of the β s could be used to simulate the effects of changes in the limit L on total savings, not just the effect on tax-deferred savings. Estimation of the S_1 function is treated in this paper.⁴

B. Independent Analysis of Contributions to Tax Deferred Savings Accounts

Within the general framework described above, one can treat separately the tax deferred saving equation. Careful treatment of that component of the more general specification is the subject of this section. There are at least two important issues to address in analyzing the determinants of IRA contributions. One is simply that in addition to the

upper limit on contributions many individuals, indeed the majority, do not contribute at all to IRA (or Keogh) accounts. The standard way to conduct the analysis in this situation would be to use a Tobit model with a lower truncation point at zero and an upper truncation point at the contribution limit. The second issue, however, is that the determinants of whether one contributes at all may be different from the determinants of how much one contributes once an account is established. While it is true that the short run effect of changes in contribution limits on total contributions is determined only by initial contributors, there may be considerably more room to change total contributions through increasing the number of persons who contribute than by increasing the contributions of current contributors. It is important, therefore, to understand the determinants of the contributor status decision.

1. Key Issues

To provide accurate predictions of the determinants of IRA contributions and of the effect on contributions of changes in the existing contribution limits, the most important consideration in estimation is to account for the existing limit on observed contributions. Thus, an intuitive discussion of the effect of the limit on estimation, together with procedures that can be used to correct for it, helps to put the important ideas in perspective, although part of the discussion will be familiar to many readers. Mathematical details of the estimation procedure are presented in appendix A.

Consider first the diagram in figure 1. Suppose that the

relationship between income and IRA contributions if there were no contribution limits would be represented by the line $a + bY$. That is, given Y the average (expected) contribution would be $a + bY$. Of course, for any level of income Y there would be a distribution of contribution levels, represented by the wavy vertical lines; not everyone with income level Y would contribute the same amount. Now suppose that everyone in the sample faced a contribution limit L . We would now observe no contributions above L and presumably individuals who otherwise would contribute above this limit would in the face of the limit contribute at the limit. This would give rise to a concentration of contributions at the limit, indicated by the heavy dots at that level. In addition, it is not possible to contribute less than zero; we would observe a concentration of points at zero, indicated by the heavy dots along the horizontal axis. If we think of fitting a line, say by least squares, to the data points that are actually observed, we would obtain a fitted line something like the dashed line in the diagram.

Suppose that from this fitted line we attempted to predict the relationship between income and contributions S . It is easy to see that this estimate would be a very substantial underprediction. Thus it is clear that standard estimation procedures will not lead to plausible conclusions in this case. And it should also be clear from the diagram that the reason is that observed observations do not represent the contributions that individuals would like to make were they not constrained by the limit.

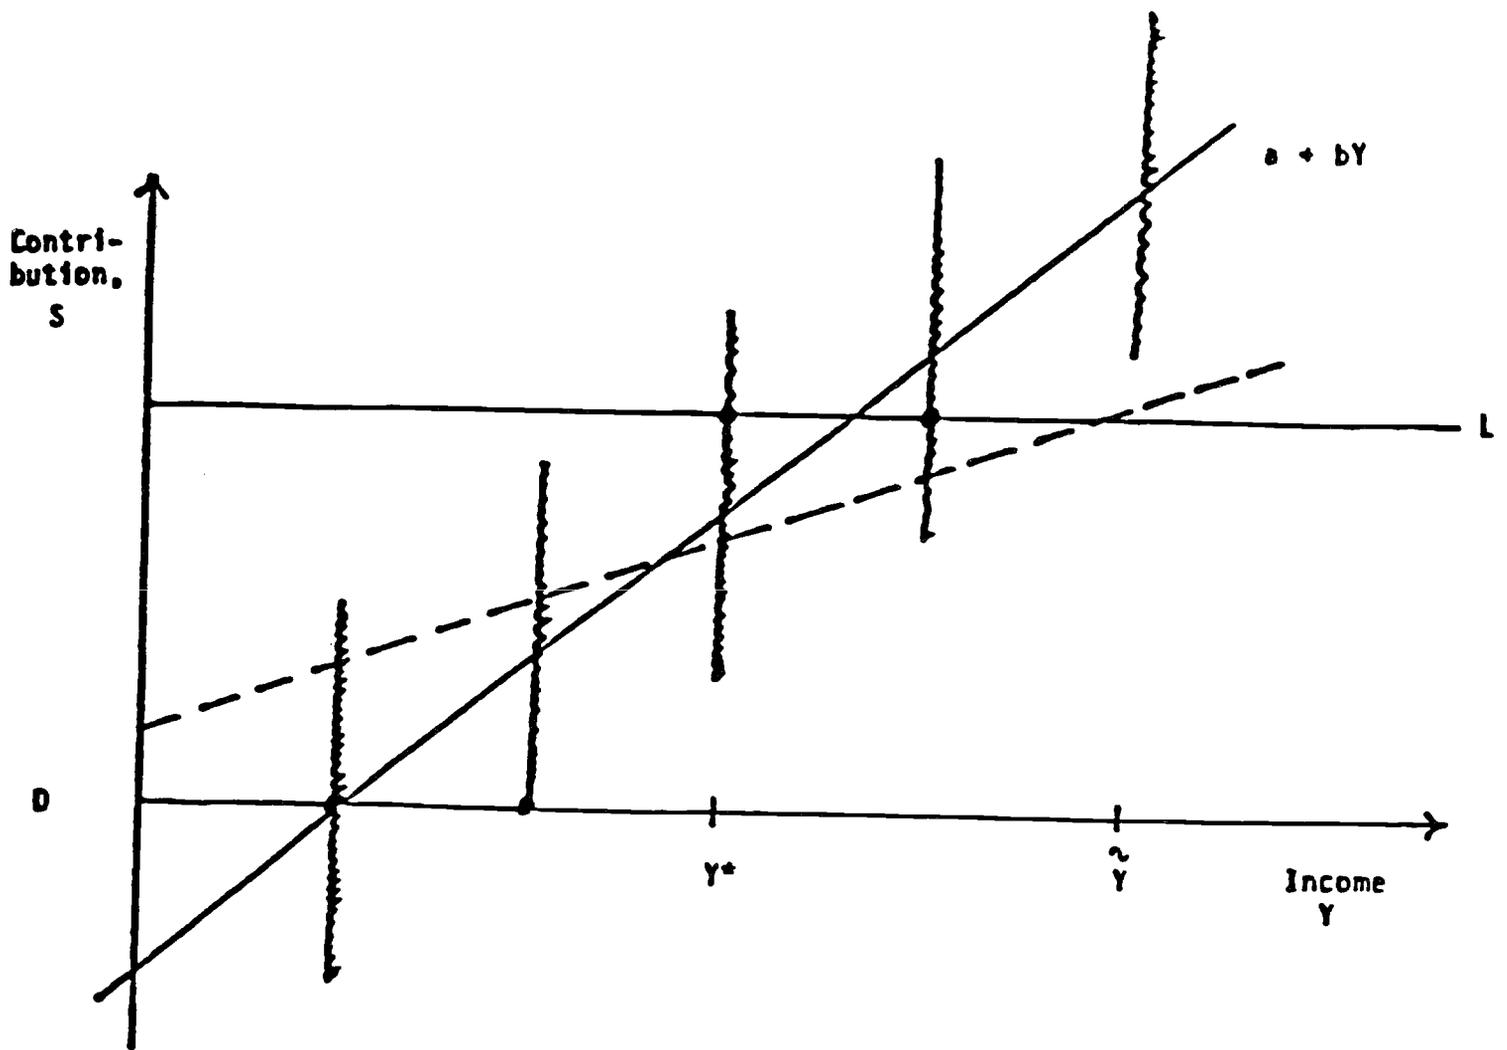

Figure 1. Illustration of Effect of Contribution Limits on Estimation

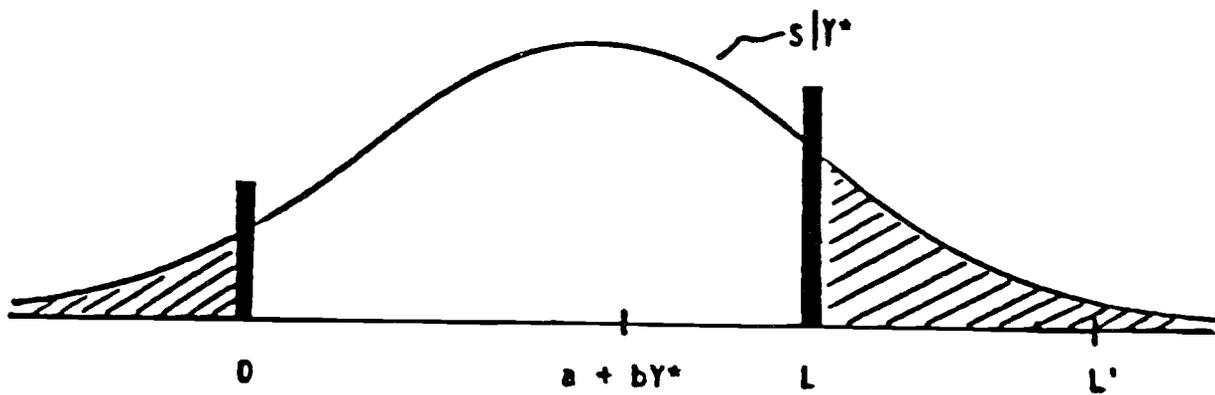

Figure 2. Illustrative Distribution of Contributions, Given Income Level Y^* .

It is useful also to consider the distribution of contributions for persons with a particular level of income, say Y^* . An illustrative distribution is shown in figure 2. If it were not for the limit at L and the limit at zero, the distribution of contributions S would look something like the bell-shaped curve, but as demonstrated in the figure above, we know that we will not observe observations greater than L , and we will observe no observations less than zero. The distribution of observed observations between zero and L would look just like the underlying curve. But instead of a distribution tapering off smoothly to the right and to the left, there would be concentrations of observations at L and at zero.

The standard Tobit maximum likelihood estimation procedure that takes account of this truncation effect is based on an assumed underlying relationship like $a + bY$, as shown in figure 1, together with a distribution of contributions around this relationship. In this case there are three possible outcomes: the contribution is zero, it is between zero and L , or it is at L . The values of a , b , and σ that maximize the likelihood of observing the sample values yield estimates of the relationship labeled $a + bY$ in figure 1, as well as the dispersion of underlying observation around this expected value. Thus the estimates that are obtained need to be interpreted as pertaining to this underlying relationship. For example, b indicates the relationship between Y and S if there were no limit on contributions. Or, it tells us how an increase in income would affect contributions as long as the contribution limit were not reached; after that, contributions would be observed at the limit L but

desired contributions would be above L.

It is also important to realize that only persons who are constrained by the current limit will be affected by a new higher limit. (If the limit is lowered, of course, increasingly large numbers of people will be constrained by it.) With the help of figure 2, it is easy to determine the effect of small changes in L on contributions. Consider first an individual whose observed contribution is less than L. Such an individual could contribute more but chooses not to; he is not constrained by the limit. His desired contribution level is less than L. So raising the limit would not increase his contribution level. Consider on the other hand a person who is observed to contribute at the limit L. If L were raised, this person would likely contribute more. Thus the effect of raising the limit by 1 is just 1 times the probability that the individual is constrained by the limit. Somewhat more formally, we can write the derivative as

$$\begin{aligned} \frac{dC}{dL} &= \begin{cases} 0 & \text{if } C < L \\ 1 & \text{if } C > L \end{cases} \\ (5) \quad &= 0 \cdot \Pr[C < L] + 1 \cdot \Pr[C > L] \\ &= \Pr[C > L] . \end{aligned}$$

Thus for any individual the expected change in the contribution level is equal to the probability that his underlying desired contribution is greater than L.

It is also important to realize that this derivative depends upon the level of L. Suppose that L were farther to the right than is shown in

figure 2, say at L'. The effect on contributions of an increase in the limit from L' would be much smaller than the effect of an increase from L because the likelihood that an individual with income Y^* would like to contribute more than L' is much lower than the likelihood that he would like to contribute more than L. While all people, or almost all people with observed contributions at L would increase their contributions if the limit were raised, very few would increase their contributions to the level L'. Thus to infer the effect of an increase in the limit on contributions, it is necessary to have an estimate of the underlying distribution of desired contribution levels. With an estimate of the distribution of S given Y^* , it is possible to predict the expected contribution given Y^* for any level of L.

2. Estimation Possibilities

In practice, estimates that address the issues motivated above can be developed in several ways, depending on the hypothesized underlying process that leads to observed contributions. There are two basic possibilities. One possibility assumes, as in the discussion above, that zero contributions can be thought of simply as a special case of a single underlying preferred contribution behavioral relationship. That is, one could think of a preferred contribution level that declines continuously with decreases in income until the zero contribution level is reached. The other general possibility is that there are two underlying behavioral relationships that determine observed contributions: one relationship describes the likelihood that a person will be a contributor and the second

relationship describes the desired contribution, should he be a contributor.

If only one behavioral relationship is assumed, there are at least three ways to obtain estimates. The alternative procedures allow a test of the underlying assumption itself. One procedure uses all observations including those with zero contributions; the second uses only observations with positive contributions; and the third uses only the information on whether a person contributes without using the amount of a positive contribution.⁵ If there is, in fact, only one underlying relationship that determines observed contributions, then each of these methods yields consistent estimates of the parameters of this single relationship (except for the third which yields estimates up to a variance scaling factor). If the estimates based on the different groups of observations lead to different estimates, then it is likely that the underlying process should be described by two relationships.

If the goal of the analysis were only to predict the effect of changes in the limits, it is reasonable to concentrate on those who contribute and to allow the parameter estimates to be determined by this group, since noncontributors are not initially affected by changes in the limit. It is at least as important, however, to understand the factors that determine whether a person is a contributor. As emphasized above, changes in the number of contributors at any limit could have a much greater effect on savings than changes in the limit. To the extent that the determinants of whether one is a contributor are different from the determinants of the amount of the contribution, it is important to consider

both of these relationships. The formal details of a two equation model, together with details of the single equation estimation possibilities and related tests of behavioral assumptions are presented in appendix A.

C. The Empirical Specification

In the illustrative specification in section A above, desired contributions to the tax-deferred savings account are of the form $S = \beta Y$. A direct statistical counterpart of this specification is:

$$(6) \quad S = \beta Y e^\epsilon = a Y^b \cdot Y \cdot e^\epsilon = \alpha_0 X_1^{\alpha_1} X_2^{\alpha_2} \dots Y^b \cdot Y \cdot e^\epsilon$$

Based on estimates for Canada, this specification fits the observations on positive contributions extremely well. Note that the specification implies that given Y (and the other variables X) the variance of S increases with Y ; the disturbance term is heteroscedastic. The specification also leads to a constant income elasticity and is conveniently linear in logs. However this specification is not appropriate if we incorporate contributions at zero and, in the abstract, the possibility of desired contributions less than zero. To consider whether the determinants of contributor status are different from the determinants of the amount of positive contributions, a specification that in principle allows negative as well as positive values and one that also fits the observations on positive contributions must be used. Such a specification, and one that in practice fits the observed data well, is of the form

$$(7) \quad \begin{aligned} S &= a + (Y^b + \eta)Y + \epsilon \\ &= \alpha_0 + \alpha_1 X_1 + \alpha_2 X_2 + \dots + Y^{1+b} + \eta Y + \epsilon \end{aligned} ,$$

where η and ϵ are disturbance terms and the variance of $\eta Y + \epsilon$ is given by

$$(8) \quad V(\eta Y + \epsilon) = \sigma_{\eta}^2 Y^2 + \sigma_{\epsilon}^2 = \sigma^2$$

Thus the specification incorporates the property that the variance of S increases with income, and it also allows for "desired" contributions less than zero. The elasticity of desired contributions with respect to income is given by $(1 + b) \div (1 + a/Y^{1+b})$ and thus approaches $1+b$ as income increases.⁶

For simplification, appendix A, that describes the details of the alternative estimation procedures, is written in terms of the specification $S = X\beta + \epsilon$, where $V(\epsilon) = \sigma^2$. Development in terms of the above specification may be obtained by replacing $X\beta$ by $a + Y^{1+b}$ and σ^2 by $(\sigma_{\eta}^2 Y^2 + \sigma_{\epsilon}^2)$. Recall that the three single-equation approaches use: (a) all observations including those with zero contributions (two-limit Tobit); (b) only observations with positive contributions (one-limit Tobit); and (c) only information on contributor status (probit). A two-equation model that jointly estimates contributor and contribution outcomes is also described in appendix A. This model permits the determinants of whether a person contributes to differ from the determinants of the desired level of a positive contribution and allows the stochastic components of the two choices to be correlated.

In addition, the CPS data on IRA contributions are reported only by interval -- 0, 0 to 100, 100 to 500, 500 to 1000, 1000 to 2000, etc. Thus the probabilities of positive contributions are of the form

$$(9) \quad \Phi[(u - X\beta)/\sigma] - \Phi[(l - X\beta)/\sigma] \quad ,$$

where u and l are the upper and lower bounds of an interval and $\Phi(\cdot)$ denotes the standard normal distribution function. Thus the likelihood function in this case includes no density function terms; it is composed only of normal cumulative distribution functions. This may be contrasted with the Canadian data that record exact positive contributions.

III. Results

A. Data

The data were obtained through a special supplement to the May 1983 Current Population Survey. The data on IRA contributions pertain to the 1982 tax year. No information is provided on 1982 contributions to Keogh plans. Thus self-employed persons have been excluded from this analysis. In addition, the raw data pertain to individuals, not families. Some of the estimates reported below are based on the individual data, with indicator variables for marital status and sex. Since it is not known from the person data whether an individual's spouse works, the actual upper limit on family contributions cannot be determined from the individual data alone. Some individuals reported contributions greater than \$2,000 -- primarily at \$2250 and at \$4000, apparently confusing individual contributions with the family total. When the individual data are used, contributions above \$2000 are not explicitly recorded at that level, but rather any reported contribution above \$2000 is treated as a contribution at the \$2000 limit. Under the model assumption, this procedure still yields

unbiased parameter estimates; it simply does not use all information.

Family data were created by matching and combining information for individuals in the same household. This allows estimation of family income and of family IRA contribution limits based on the employment status of the husband and wife. Estimated marginal tax rates were also calculated for the family. The estimates were based on average marginal tax rates by income and family status reported by the IRS. As mentioned above, IRA contributions for each family member are reported only by interval. The intervals for a family were obtained by inferring the possible family intervals from the possible individual reporting intervals. There are 12 possible family intervals in total. Details of the procedures used to create the family data and the tax rates are reported in appendix B.

B. Parameter Estimates: Single Equation Models

1. Person Data

Estimates by method of estimation are reported in tables 6 and 7. Summary statistics for the variables included in each equation are presented in appendix table 1. Table 7 includes variables indicating whether a person was covered by a private pension plan and whether the worker participated in a salary reduction plan (401(K) or 403(B) plans which permit workers to defer compensation); these variables are not included in table 6. The first column in each table presents estimates based on the two-limit Tobit specification. The second column shows probit estimates where the standard error of ϵ is set at the two-limit Tobit estimate (e.g., 5622 in table 6). This allows easy comparison of the two sets of estimates. It

may be seen that the parameter estimates are virtually the same. Whether there is a difference between the determinants of contribution status and the determinants of the desired level of IRA contribution may not be revealed by this comparison, however, since the preponderance of individuals make no contribution and thus the contribution status (the probit portion) will dominate the two-limit estimates. The two-limit Tobit estimates will therefore tend to look like the probit estimates.

A better way to reveal differences in the two relationships is to separate analysis of contribution amounts from the analysis of contributor status. The 1-limit Tobit estimates in column three of the tables are based only on the contributions of contributors, and the probit estimates of contributor status in column 4 are obtained by setting the standard error of ϵ equal to the one-limit estimate (e.g., 2026 in table 6). These last two columns reveal that the two sets of coefficients are quite similar. The reported coefficient on income is the estimate of $(1 + b)$. It is virtually the same in each of the alternative methods, and the estimated parameters on age seem not to be significantly different in the two cases. The estimated sex effects are also very close in the two cases, with one exception. The estimates suggest that unmarried men contribute more than married men but are apparently no more likely than married men to contribute. The constant terms in the two equations differ, although given the estimated standard errors, the difference may not be as great as the estimated values suggest.

A more formal test is to compare the sum of the likelihood values from columns 3 and 4 with the likelihood value in column 1. Under the null

hypothesis that one behavioral relationship is sufficient to describe both contributor status and the amount of contributions, the sum of the likelihoods in columns 3 and 4 will not be statistically different from the likelihood value in column 1. Minus 2 times the difference will be distributed chi-square with 7 degrees of freedom, with a .05 level of 14.1. Thus, the hypothesis would be rejected in this case. However, the very large sample size will reveal differences even if they have rather small practical importance.

The coefficient on income of .753 implies an elasticity of desired contribution with respect to income of .63, evaluated at the mean of the data for contributors. The desired contribution increases by about \$110 with each year of age according to the estimates for contributors, while the comparable estimate from the probit equation is \$81. Given other variables, married women would choose to contribute about \$1000 more than married men and the more educated would contribute more than those with less education. The estimated unmarried women effect is not statistically significant.

Summary statistics presented earlier in table 5 suggested that employees covered by a private pension plan were more likely to contribute to an IRA. Parameter estimates in table 7, however, suggest that the association between pension coverage and IRA contributions can be attributed to other differences in the individual characteristics of those covered and not covered by a pension plan. After controlling for other characteristics, pension plan coverage is not significantly associated with desired contributions. Participation in a salary reduction plan (less than

4 percent of the sample) is positively associated with IRA contributions.

Both the two-limit and the one-limit models fit the data rather well. This is demonstrated in table 8. Based on the estimates in table 6, the predicted proportion of individuals with contributions at zero, at the upper limit, and within selected intervals are compared with the actual proportions, by income interval. It is important in interpreting these results to realize that gross misspecification of the functional form that relates contributions to income would be revealed in the comparisons by income level. The comparisons indicate close correspondence between predicted and actual proportions. The only apparent discrepancy is that the two-limit Tobit specification underpredicts the proportion of contributions in the \$1000 to \$2000 range and correspondingly overpredicts the proportion of contributions at the limit. Given the differences between a few of the two-limit and one-limit parameter estimates, the similarity of the predictions may be surprising. However, the major difference in parameter estimates is a larger negative constant term in the two-limit than in the one-limit specification, that is offset by a larger disturbance term variance. The likelihood function is quite flat with respect to these two parameters. Thus the sum of the last two likelihoods is not in magnitude so different from the two-limit Tobit likelihood.

2. Family Data

Parameter estimates based on the family data are reported in table 9. The variable specification is identical to that used for the person data

Table 8. Model Fit; Actual versus Predicted Proportions by Income Interval, Contribution Interval, and Method of Estimation^a

with two exceptions: the marginal tax rate has been added and the dummy variable for "married-women" has been deleted, with non-single-person families the norm group. Married men and women appear together in the family data, but as two separate observations in the person data.

Where the variables are the same, the parameter estimates are very similar to those based on the person data. For example, the estimated income coefficient based on the two-limit tobit model is 0.78 using family data and 0.84 using person data. The effects of age and education are also quite close.

The results suggest no effect of the marginal tax rate on the amount of contributions but a positive effect on contributor status. The coefficient on the estimated marginal tax rate in the two-limit specification is 200 with a standard error of 39. This would suggest that an increase of 10 percentage points in the marginal tax rate would increase desired IRA contributions by about \$2000. On the other hand, the one-limit and probit estimates in the last two columns suggest that the tax rate has no effect on the level of contributions (column 3) but a positive effect on contributor status (column 4). The latter estimate implies that if all marginal tax rates were increased by 10 percentage points -- on average from about 24 to 34 -- the proportion of persons who contribute would increase from .134 to .193, or by 44 percent.

Canadian estimates for 1981 (reported below) show a much smaller statistically significant effect of the marginal tax rate on contributor status, with a smaller and not statistically significant effect on the

amount of contributions. (But the difference between the two estimates is also not significantly different from zero.) Canadian estimates for 1976 show no effect of the marginal tax rate in either equation.⁷ An alternative log-linear model for contributors only shows a precisely estimated zero effect of the marginal tax rate on the amount of contributions in both 1976 and 1980. Thus the estimated effect seems quite sensitive to the statistical specification.

Table 10 includes indicators of pension coverage and participation in a salary reduction plan. These estimates indicate that if at least one member of a family is covered by a pension plan, the likelihood of contributing to an IRA is higher. The person data suggested essentially no relationship. A possible explanation is that married persons without pensions, but whose spouses are covered by a pension, have a high likelihood of contributing to an IRA. In the person data, these people would be treated as not having a private pension.

C. Simulations: Single Equation Models

Simulations are obtained under three policy assumptions: the existing IRA program, the proposal contained in the administration's recent tax reform proposal (U.S. Department of Treasury [1984]), and a modification of the Treasury proposal that restricts spousal IRAs. The Treasury proposal increases the limits to \$2500 for both employed persons and nonemployed spouses. The modified Treasury proposal also increases the limit for employed persons to \$2500 but sets the spousal limit at

\$500, instead of \$2500.

Simulations based on the family data are presented in table 11.⁸ To serve as a base for comparison the average IRA contribution under the current plan has been simulated for several demographic groups. The model yields an average predicted contribution for all families under the current plan of \$312.⁹ The simulations indicate that the Treasury plan would increase 1982 contributions by 30 percent to \$405 per family. The largest increases are for a married-one-earner families whose limit is increased by the Treasury proposal from \$2250 to \$5000. The predicted average contribution for this group would increase from \$267 to \$475, about 78 percent. The smallest increase, about 16 percent, is for "married-two-earner" families whose limit increased only from \$4000 to \$5000.

The modified Treasury plan yields an overall increase of about 18 percent. The limit changes, and thus contributor responses, for unmarried heads and married-two-earner families are the same as in the unmodified Treasury proposal. The modified Treasury plan increases the limit faced by married-one-earner families by only \$750, from \$2250 to \$3000, instead of \$5000. The simulated increase in average contributions by this group is 25 percent, about a third as large as the simulated increase under the Treasury plan.

Simulations based on the person data are shown in table 12. Unlike the family data, the person data do not provide enough information to completely specify the limit faced by each person. Employed single persons

Table 11. Simulated IRA Contributions, by Plan and Family Type, Based on Family Data ^a

face a limit of \$2000. For married couples the limits are \$2000 per person if both work and \$2250 if only one works. If both work, then both will appear in the sample and the appropriate limit for each is \$2000. If only one is employed, however, the nonemployed spouse will not be present in the sample, since only employed persons received the CPS pension supplement questionnaire. The appropriate limit for the employed spouse is \$2250. The problem is to assign the "correct" limit (\$2000 or \$2250) to each married person in the sample given that we do not know if the spouse is employed.¹⁰ If the married person is a woman, a limit of \$2000 is assigned, assuming that her spouse also works. If the married person is a man, the limit is randomly assigned. With probability P it is set at \$2000 and with probability $1-P$ at \$2250, where P is the proportion of wives of working husbands that are employed.

The person data simulations based on this procedure are quite close to those obtained using the family data. For all persons, the simulations indicate the Treasury plan will increase 1982 contributions by about 33 percent and the modified Treasury plan will increase contributions by about 20 percent. The largest effects are for married men, the group facing the largest change in limits.

D. Parameter Estimates: Two Equation Model

The above results suggest that the observed outcomes can in general be described well with a single behavioral relationship. If two relationships are required, the one-limit Tobit and the probit models

together, even if estimated independently, should provide a reasonably accurate description of the determination of contributions. The two-equation model described in appendix A, however, distinguishes between a "potential" contributor behavioral relationship and the level of desired contributions, were one to contribute. Under this representation, a potential contributor could be observed with zero contributions not because the person was a non-contributor, but rather because income say was too low for the person to devote current income to future consumption. To the extent that the parameters in the two relationships differ, the single-equation probit estimates, for example, will not provide accurate estimates of potential contributor status. As the parameters in the two relationships become close, and the correlation between them approaches 1, however, the two-equation model approaches the two-limit Tobit specification. If only the variable coefficients were the same, the results could differ if the correlation between the disturbance terms in the two relationships were not unity.

Estimation of several two equation models indicated only minor differences between parameters based on the single equation models and those derived from two relationships estimated jointly. The two equation model is of the form

$$S = a_s + Y^{b_s} + \eta_s Y + \epsilon_s \quad \text{Contributor Status}$$

$$C = a_c + Y^{b_c} + \eta_c Y + \epsilon_c \quad \text{Contribution Amount}$$

The details of the specification and estimation procedure are described in section II of appendix A. The key distinction between the specification

used here and the common sample selection specification is that even potential contributors can have zero contributions, while others would not contribute under any circumstances. Only the latter are "non-contributors" in the strict sense.

Illustrative estimates for this model are presented in table 13. In this specification, $V(\eta_C) = V(\eta_S)$, $V(\epsilon_C) = V(\epsilon_S)$, and all covariances other than $\text{Cov}(\eta_C, \eta_S)$ are set to zero. Education is excluded from the contributions equation. In practice, covariance or exclusion restrictions were required for identification of key parameters. Because the likelihood function was so flat, more restrictions were necessary than were in principle required.

The parameter estimates indicate that the correlation between η_C and η_S is not significantly different from zero.¹¹ This suggests independence of the contributor and contributions relationships, given measured individual characteristics. Thus these estimates are very close to the single equation results presented in the last two columns of table 6.¹²

In principle, however, this specification allows estimation of the proportion of persons who are potential contributors but because of a liquidity constraint, for example, are observed not to contribute. The probability that a person does not contribute is given in this specification by $1 - \Pr[S < 0] + \Pr[S > 0 \text{ but } C < 0]$. Averaged over all observations in the sample, the proportion of non-contributors is .854, the same as in the probit estimates based on person data. A proportion .146 contribute. The proportion of potential contributors, $\Pr[S > 0]$, is

estimated to be .182. Thus, the proportion of potential contributors who do not contribute, $\Pr[S > 0 \text{ but } C < 0]$, is estimated to be .036, about 20 percent of potential contributors.

IV. Comparison of Results for the United States and Canada

Since the Canadian and the American systems are very similar in their general outlines, it is informative to compare the model estimates for the two countries. The Canadian equivalent of IRA and Keogh plans is the Registered Retirement Saving Plan (RRSP). RRSP contributions are also tax-deferred and have upper limits determined both by income and by a maximum level. The Canadian rules also provide for different limits depending on whether a person is a member of a private pension plan.

Since the Canadian tax system is on a person basis, the most appropriate comparison is with the person estimates for the United States. Estimates analogous to those in table 1 for the United States are shown in table 14 for Canada. While the general model specification is identical in the two countries, the specific variables do not correspond precisely. In particular, the variables for women, married, and education are not included in the Canadian version, and there is no marginal tax rate variable in the United States version. The comparable parameter estimates, however, are surprisingly similar, based on a comparison of the one-limit Tobit and the corresponding probit estimates in the two countries. The coefficient on income is .75 in the United States, while it is approximately .81 in Canada. The estimated effect of age is

approximately \$80 to \$110 in the United States, while it is \$65 to \$80 in Canada. The estimates for Canada also indicate a close correspondence between the one-limit Tobit and the probit estimates, indicating that a single behavioral relationship apparently describes the observations rather well. Indeed for Canada the estimates in the two equations are not statistically different, based on the chi-squared test described above.

As discussed above, the estimated effect of the marginal tax rate in Canada is not statistically different from zero in the contributions equation; the estimate for the United States, reported for the family data in table 9, is also not statistically different from zero. In both countries the effect of the tax rate on contribution status is positive, although it is much smaller in Canada. As emphasized above, these results are very sensitive to model specification and it may not be possible to distinguish the effect of the marginal tax rate from a non-linear effect of income.¹³

The parameter estimates from a more highly parameterized model for Canada are shown in table 15. The variable "employee w RPP" indicates individuals in Canada with a private pension plan. Neither estimate is statistically different from zero, although the one-limit estimate is quite negative. In the United States, there appears to be no relationship between pension coverage and IRA contributions based on the person data, although there is some evidence of a positive pension relationship in the family data.

Because data in Canada are available for several consecutive years,

it is possible to check the validity of the model specification for that country. Between 1976 and 1981, the Canadian Consumer Price Index increased by about 60 percent, but RRSP limits did not change over the period. Thus in real terms the limits declined very substantially between the years. Thus a good external check of the predictive validity of the model is to use estimates for one of the years to predict contributions in the other, when the limit was either considerably higher or much lower. Such predictions, using the two-limit and the one-limit estimates reported in table 15, shown in table 16. In general the predicted values are very close to the actual ones. For example, one-limit estimates for 1981 underpredict 1976 contributions by only 1.7 percent, and one-limit estimates for 1976 underpredict 1981 contributions by only 1.1 percent. Estimates based on the two-limit model also yield predicted values very close to actual values. Since the parameter estimates in the two countries are rather close, this suggests that the model should predict rather well in the United States as well.

V. Conclusions

Persons with low incomes are unlikely to have IRA accounts. In addition, after controlling for income, age, and other variables, persons without private pension plans are no more likely than those with them to contribute to an IRA. Indeed, if anything, those with private plans contribute more than those without them. Both contributor status and the amount of positive contributions are determined in large part by income and

to a lesser extent, demographic characteristics. The marginal tax rate may have a positive effect on whether one contributes, but does not appear to influence the contribution amount. Results based on different specifications suggest that it may be difficult to distinguish the effect of the marginal tax rate from a non-linear income effect. Simulations based on the estimates suggest that the current Treasury Department proposal would lead to about a 30 percent increase in IRA contributions.¹⁴ Model estimates based on Canadian data for RRSPs are very similar to those for the United States. External checks of the predictive validity of the model for Canada indicate that predictions of the effects of limit changes are quite accurate.

Appendix A: Estimation of IRA Contributions

To estimate IRA contributions, there are two possibilities: the first is to assume that one underlying behavioral relationship leads to all of the observed outcomes. In this case there are three ways to estimate the same parameters and the difference between the estimates can serve as a basis for a test of the assumption that one behavioral relationship is sufficient. If it is not, the second method is to assume that observed behavior results from two behavioral relationships, one pertaining to the decision to be a contributor and the other describing the desired amount to contribute, were one a contributor. They are described in turn. The first is familiar to many readers and the goal is simply to make clear that, under the maintained hypothesis, the three approaches all yield estimates of the same parameters. The second approach is not as familiar, but is a generalization of a similar procedure in Deaton and Irish [1984].

I. A Single Behavioral Relationship

Assume the following notation:

s \equiv Observed contribution,

S \equiv Latent contribution "propensity,"

X \equiv Vector of individual attributes,

L \equiv Contribution limit,

ϵ \equiv Random disturbance term,

i \equiv Indexes individuals.

Latent contributions are specified as

$$S_i = X_i \beta_1 + \epsilon_i \quad ,$$

where ϵ_i is assumed to distributed normal with mean zero and variance σ^2 .

Precise amounts contributed by each individual to an IRA are not reported. Instead, we know if the individual did or did not contribute and, if a contribution was made, the interval in which the contribution falls. Details on the intervals are presented in appendix B. The intervals may be summarized as:¹⁵

$$\begin{aligned} s_i &\leq L_0 \\ L_{t-1} &< s_i < L_t \quad t = 1, T \\ L_T &\leq s_i \end{aligned}$$

where, in the "person" data $T = 3$ and $L_0 = \$0$, $L_1 = \$500$, $L_2 = \$1000$, and $L_3 = \$2000$. In the "family" data $T = 12$.

A. Two-Limit Tobit¹⁶

When all of the observations are used, there are $T + 2$ possible outcomes -- contributions at zero, contribution within each of the T closed intervals, and contributions at the upper limit. These outcomes and associated likelihoods are:

$$\begin{aligned} (i) \quad s_i = 0, & \quad \Phi\left[\frac{-X_i\beta}{\sigma}\right] \\ (1) \quad (ii) \quad L_{t-1} < s_i < L_t & \quad \Phi\left(\frac{L_t - X_i\beta}{\sigma}\right) - \Phi\left(\frac{L_{t-1} - X_i\beta}{\sigma}\right) \quad t = 1, T \\ (iii) \quad s_i = L_T, & \quad 1 - \Phi\left[\frac{L_T - X_i\beta}{\sigma}\right] \end{aligned}$$

where $\Phi[\cdot]$ denotes the standard normal distribution function.

B. One-Limit Tobit with Zeros Excluded

When the zero values are excluded, there are $T + 1$ possible outcomes: the contribution lies within one of the T intervals or at the upper limit. These outcomes and associated likelihood are:

$$(2) \quad \begin{aligned} (i) \quad L_{t-1} < s_i < L_t & \quad \left\{ \Phi\left(\frac{L_t - X_i\beta}{\sigma}\right) - \Phi\left(\frac{L_{t-1} - X_i\beta}{\sigma}\right) \right\} / \Phi\left[\frac{X_i\beta}{\sigma}\right] \quad t = 1, T \\ (ii) \quad s_i = L_T & \quad \left\{ 1 - \Phi\left[\frac{L_T - X_i\beta}{\sigma}\right] \right\} / \Phi\left[\frac{X_i\beta}{\sigma}\right] \end{aligned}$$

The demoninator in each expression, the probability of a positive contribution, reflects the fact that noncontributors have been excluded from the analysis. In a single equation model, the underlying distribution of contributions is truncated at zero when the one-limit Tobit specification is used, while there is a mass point at zero when the two-limit version is used.

C. Simple Probit

Finally, estimates can also be obtained with a simple probit specification (up to the scale factor σ). In this case the outcomes and associated likelihoods are

$$(3) \quad \begin{aligned} (i) \quad s_i = 0 & \quad \Phi\left[\frac{-X_i\beta}{\sigma}\right] \\ (ii) \quad s_i > 0 & \quad \Phi\left[\frac{X_i\beta}{\sigma}\right] \end{aligned}$$

D. Likelihood Function

If there are N_0 observations at zero, N_t observations in interval t , and N_{T+1} observation at the upper limit, the log-likelihood function in each of the three cases is:

$$(A) \quad \ln L = \sum^{N_0} \ln \phi \left[\frac{-X_i \beta}{\sigma} \right] +$$

$$\sum_{t=1}^T \left\{ \sum^{N_t} \ln \left[\phi \left(\frac{L_t - X_i \beta}{\sigma} \right) \right] - \phi \left(\frac{L_{t-1} - X_i \beta}{\sigma} \right) \right\} +$$

$$\sum^{N_{T+1}} \ln \left[1 - \phi \left(\frac{L_T - X_i \beta}{\sigma} \right) \right]$$

$$(B) \quad \ln L = \sum_{t=1}^T \left\{ \sum^{N_t} \ln \left[\left\{ \phi \left(\frac{L_t - X_i \beta}{\sigma} \right) - \phi \left(\frac{L_{t-1} - X_i \beta}{\sigma} \right) \right\} / \phi \left(\frac{X_i \beta}{\sigma} \right) \right] \right\} +$$

$$\sum^{N_{T+1}} \ln \left[\left\{ 1 - \phi \left(\frac{L_T - X_i \beta}{\sigma} \right) \right\} / \phi \left(\frac{X_i \beta}{\sigma} \right) \right]$$

$$(C) \quad \ln L = \sum^{N_0} \ln \phi \left[\frac{-X_i \beta}{\sigma} \right] +$$

$$\sum_{t=1}^{T+1} \left\{ \sum^{N_t} \ln \phi \left(\frac{X_i \beta}{\sigma} \right) \right\}$$

It is clear that (B) + (C) = (A) under the one-equation assumption. If this assumption is inconsistent with the data, the β estimated from (B) will differ from the β estimated from (C). In addition, to the extent that they differ, the sum of the likelihoods values from (B) and (C) will

be greater than the value from (A) since the "separated" models allow a better fit to the data. Thus a test of the one-equation behavioral assumption can be based either on a comparison of the estimated β 's or on the likelihood values. If they differ, a specification with two behavioral equations may be indicated.

II. IRA Contributors and Contributions: A Two-Equation Model

The purpose of this section is to describe a procedure that can be used to relax the one-equation constraint. It is assumed that two behavioral relationships determine the contributions that we observe. One is a relationship between individual attributes and the likelihood that a person is a potential IRA contributor. The other is a relationship between individual attributes and the level of desired contributions, were one to contribute. Of course, both of the outcome variables should be thought of initially as latent variables. In particular, if the latent contribution variable is less than zero, we shall assume that we observe no contribution, even if the contributor latent variable is greater than zero. A desirable property of the model is that it encompasses as a limiting case the standard Tobit model of section I.

The model is described by:

$$C = X\beta + \epsilon \quad ,$$

$$S = X\alpha + \eta \quad ,$$

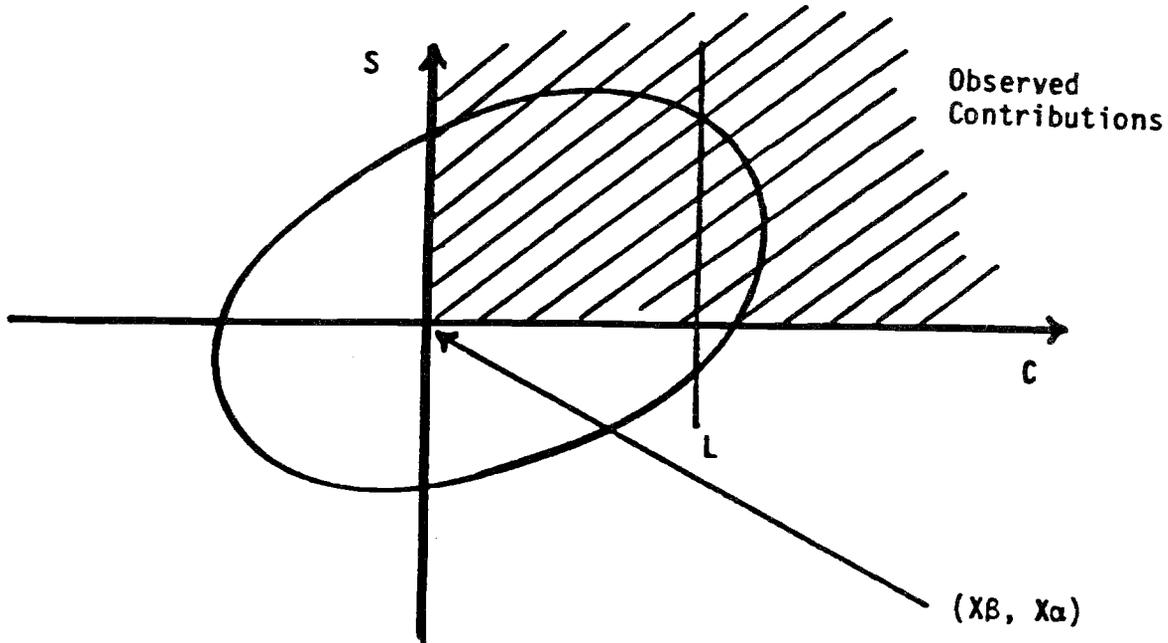

where C is the latent contribution variable and S the latent contributor variable, X is a vector of individual attributes, β and α are vectors of parameters to be estimated, and ϵ and η are disturbance terms.¹⁷ We assume

that given X, C and S obey the covariance matrix:

$$\Sigma = \begin{bmatrix} \sigma^2 & \rho\sigma \\ \rho\sigma & \sigma^2 \end{bmatrix},$$

where ρ is the correlation between C and S, given X.

The bivariate distribution between S and C is represented graphically in the figure below. The figure includes the limit on IRA contributions L. That is, as usual, we will not observe contributions above L but will observe a

concentration at the level L. We shall assume that a person is a contributor if the latent contributor variable S is greater than zero, and his desired contribution amount is greater than zero. Thus when S and C are both greater than zero we observe IRA contributions greater than zero but less than or equal to L.

As in the usual Tobit case, there are three observable outcomes: IRA contributions are zero, contributions are at some level C where C is greater than zero but less than L, or we observe C at the limit L. The likelihoods associated with these three outcomes are now

<u>Outcome</u>	<u>Likelihood</u>
C = 0	$\Pr[S < 0] + \Pr[S > 0 \text{ and } C < 0]$
$L_{t-1} < C < L_t$	$\Pr[S > 0 \text{ and } L_{t-1} < C < L_t], t = 1, T$
C = L	$\Pr[S > 0 \text{ and } C > L]$

They are described in somewhat more detail by

<u>Outcome</u>	<u>Likelihood</u>
C = 0	$\Phi[-X\alpha] + \Phi_2[X\alpha, \frac{-X\beta}{\sigma}; -\rho]$
$L_{t-1} < C < L_t$	$\Phi_2[X\alpha, \frac{L_t - X\beta}{\sigma}; -\rho] - \Phi_2[X\alpha, \frac{L_{t-1} - X\beta}{\sigma}; -\rho]$ $t = 1, T$
C = L	$\Phi_2[X\alpha, \frac{-(L_T - X\beta)}{\sigma}; \rho]$

where $\Phi_2[\cdot]$ indicates the bivariate normal distribution function.

If indeed C and S are the same underlying stochastic variable, as in the Tobit case, β goes to α and ρ goes to 1.¹⁸ Thus in this case, the two-equation description of IRA contributions reduces to the Tobit specification. By comparing the likelihood values in the two models, one can test explicitly whether the single behavioral equation version can be rejected. The difference between this test and those mentioned in section I, is that the two equations are allowed to be correlated.

Appendix B: U.S. Data Sources

All data for the U.S. is from the May 1983 CPS and Supplemental Survey of Pension and Retirement Plan Coverage. Two data sets were created: person and family.

A. Person Data

The CPS data is arranged by person. The sample used includes all persons meeting the following criteria:

1. Included in the supplement (working for pay)
2. Between the ages 16 and 65
3. Not self-employed
4. Containing valid responses for each of the variables used in Table 7.

All summary tables and simulations (but not the estimated models) using person data use the CPS weights designed to represent the nation as a whole. No adjustment to these weights was made for exclusion of observation due to invalid responses.

Several problems arose with the way the IRA variables were coded. Employed persons were asked "Do you have an IRA?". Those answering in the affirmative were then asked: "Approximately how much of your own IRA did you credit to your 1982 Federal taxes?" Responses are coded in the intervals:

under \$100
\$100 - \$499
\$500 - 999
\$1000 - 1999
\$2000 - 2499
\$2500 -

This categorization led to two problems. First, a surprisingly large number of persons reported IRA contributions in the first (under \$100)

category. Most of these responses probably indicate persons establishing IRAs prior to 1982 and making no contribution in 1982. We have thus interpreted the first category to indicate zero contributions in 1982.

Second, a small number, 186, of respondents indicated a contribution exceeding \$2500. These responses presumably reflect family rather than own contributions. These observations have been deleted from our sample.

B. Family Data

For tax status the family is a more appropriate unit than the person in the United States. Using relationship codes, ages, and marital status we have converted the CPS data to a family basis. The incidence of unclassifiable persons or otherwise inconsistent units was rather high. In such cases, the observations were deleted from the sample.¹⁹ One consequence is that use of the CPS weights is no longer appropriate.

There are two important advantages to forming a family based sample. The first is that the employment status of husband and wife in two-person families can be determined. This permits unambiguous assignment of contribution limits used to simulate policy changes.

The second advantage is that marginal tax rates can be calculated based on the family information. Our calculations are based on U.S. Internal Revenue Service [1984], Statistics of Income for 1982. This source reports average adjustments and deductions by income category. The first step is to convert each family's reported total income to adjusted

gross income by accounting for average adjustments (excluding IRAs and Keoghs) by income class. To obtain taxable income, personal exemptions (\$1000 for self, spouse if married, and each child) and the average itemized home mortgage interest deduction (in excess of the standard deduction if one were not to itemize) for families reporting owning a home are subtracted from gross income. Finally, 1982 tax tables by filing status provide the marginal tax rates assigned to each family. These calculated rates span the entire range from zero to fifty percent.

Appendix Table 1: Summary Statistics

Variable	Person Data		Family Data	
	All	Contributors Only	All	Contributors Only

Marg. Tax Rate	--	--	24(11)	34(10)
Age ^a	37(12)	46(11)	39(13)	46(11)
Unmarried Women	.17(.38)	.10(.30)	.22(.41)	.14(.35)
Unmarried Men	.15(.36)	.08(.26)	.17(.37)	.10(.30)
Married Women	.28(.45)	.32(.47)	--	--
Education ^a	13(2.7)	14(2.6)	13(2.9)	14(2.7)
Private Pension ^b	.51(.50)	.67(.47)	.53(.50)	.78(.41)
Salary Reduc. Plan ^b	.03(.18)	.07(.26)	.04(.20)	.10(.29)

- a. In the family data the value for this variable pertains to the CPS reference person in the household.
- b. In the family data the value for this variable is one if either member participates; zero otherwise.

Notes

1. In general, under the Canadian plan persons can contribute 20 percent of income up to a maximum of \$3500 for those with a private pension plan and \$5500 for those without a private plan.

2. This may be contrasted with portfolio composition analysis most recently represented in the work by King and Leape [1984] or earlier work by Feldstein [1976] for example.

3. Given current income, contributions to tax deferred accounts could of course be taken partially or entirely from other existing asset balances. The identification problem is to determine whether this is the case. It is not possible to address this issue with the CPS data, but it will be considered in subsequent analysis based on other data sources.

4. As far as we know, a model like this one has not been estimated. In any event, data limitations and other choices in the empirical implementation would undoubtedly leave uncertainty about the effect of tax deferred accounts, as well as the effect on tax-deferred contributions of changes in the contribution limits. Answers to these questions are important in their own right and can be answered with considerable confidence.

5. By referring back to figure 2, one can see the difference between these procedures. If all the data are used, then there is a concentration

of observations at zero and at L. If the zero observations are deleted, there is no concentration of data points at zero, but the distribution is truncated at this point and the concentration at L remains. The third procedure only considers whether contributions are zero or not.

6. The preference function that corresponds to (7) is

$$V(Y-S, S) = (S/\beta)e^{[a + \beta(Y-S)]/S},$$

where $a = a_0 + a_1x_1 + \dots + a_kx_k + \epsilon$, and $\beta = Y^b + \eta$.

7. The estimates are in fact negative but not statistically different from zero.

8. Given program limits, the estimated parameters, and values of X for each member of the sample, the expected contribution of each individual or family is (following the notation of appendix B):

$$\begin{aligned} E(c) &= \Pr[C \leq 0] \cdot E[C \mid C \leq 0] \\ &+ \Pr[0 < C < L] \cdot E[C \mid 0 < C < L] \\ &+ \Pr[C \geq L] \cdot E[C \mid C \geq L] \\ &= (X\beta) \cdot [\Phi(\frac{L-X\beta}{\sigma}) - \Phi(\frac{-X\beta}{\sigma})] \\ &+ \sigma[\Phi(\frac{L-X\beta}{\sigma}) - \Phi(\frac{-X\beta}{\sigma})] + [1 - \Phi(\frac{L-X\beta}{\sigma})] \cdot L \end{aligned}$$

9. This estimate may be compared to the average IRA deduction based on IRS wage and salary returns which was \$340 for 1982.

10. Note this lack of information poses a problem for prediction but not for estimation. The statistical model used to obtain parameter estimates assigns all married persons an open-ended upper limit of \$2000 or more.

11. The implied correlation between $(\eta_C Y + \epsilon_C)$ and $(\eta_S Y + \epsilon_S)$ is about -0.01.

12. It may be noticed that the sum of the individual likelihood functions is 9490.5, whereas the likelihood value for the joint specification is somewhat higher, 9497.8. The higher likelihood value results from the equal variance restrictions on η and the exclusion of education from the contribution equation.

13. Indeed for some years the estimated effect in Canada is in fact negative, although not statistically different from zero.

14. Strictly speaking, the simulations indicate that had the Treasury proposal been implemented in 1982, contributions would have been 30 percent higher than they were.

15. In principle the open intervals can be treated as closed intervals by setting limits of $-\infty$ or ∞ . We treat open and closed intervals separately for expositional purposes only.

16. To simplify matters this appendix derives likelihood functions for a linear specification of S_i and a homoscedastic error structure. The

estimated model is based on the parameter and error structure given by equation (5) in the text.

17. In practice, this model is also estimated with a nonlinear specification with a heteroscedastic error structure, with equations analagous to those in the text.

18. First consider the $C = 0$ case. Under the limiting case, the probability of S greater than zero and C less than zero goes to zero because this would be an outcome with zero likelihood. Thus, the bivariate distribution function drops out. The $L_{t-1} < C < L_t$ and $C = L_T$ cases can be rewritten as $\Pr[S > 0 | L_{t-1} < C < L_t] \cdot \Pr[L_{t-1} < C < L_t]$ and $\Pr[S > 0 | C > L_T] \cdot \Pr[C > L_T]$ respectively. The first term in each case goes to unity in the limiting case, since if C is greater than some positive L_t , S must also be greater than zero. Thus in both cases the bivariate distribution in the last term of likelihoods reduces to expressions containing only univariate cumulative distributions.

19. For example, we eliminated persons married but living in a single person household. Heads with the other relatives but not married were treated as single persons.
